Abstract

Fibronectin (FN) is a widely distributed glycoprotein which is present in different bodily fluids, on the surface of cells and in the extracellular matrix (ECM). It plays roles in various processes, including cell adhesion, migration, growth, proliferation, and tissue repair. Fibronectin exists in 2 forms: a soluble, inactive molecule, called plasma FN (pFN), which is synthesized by hepatocytes in the liver, and an insoluble cellular form (cFN), which is produced locally by different types of cells and is a key component of the ECM. Fibrinogen fibrils ensure structural support for cell adhesion and promote cell migration, proliferation and apoptosis. Additionally, FN controls the availability of growth factors. The plasma form of FN is a crucial component of the fibrin clot in the early wound-healing response, while the cellular form of FN supports efficient platelet adhesion, activation, aggregation, and procoagulant activity. Alternative splicing of the FN gene results in the generation of protein variants which contain the additional isoforms – extra domain A of FN (EDA) and extra domain A of FN (EDB); these are associated with, e.g., tissue remodeling, fibroblast differentiation, inflammation, and tumor progression. Fibronectin also serves as a target for a large number of bacterial proteins, and as part of a 3-component bridge (FN, integrin and FN-binding proteins – FnBPs) it contributes to bacterial colonization of endothelial and epithelial cells. Fibronectin has been identified in sepsis in humans as a negative acute-phase protein, and a low level of FN seems to be a marker of a poor prognosis for a patient. Here, the role of FN in inflammatory processes and sepsis is presented.

Key words: extra domain A of fibronectin (EDA), fibronectin-binding proteins (FnBPs), inflammation, sepsis, fibronectin
Fibronectin structure

Fibronectin (FN) is a glycoprotein widely distributed in human bodily fluids, on cell surfaces and in tissues. It is a key component of the extracellular matrix (ECM). Fibronectin occurs in both soluble and insoluble forms. The concentration of FN in the blood plasma of healthy humans is approx. 300 mg/L, and this type of soluble FN – called plasma FN (pFN) – is synthesized by hepatocytes. Insoluble, cellular FN (cFN) is a component of the ECM; it is produced by different types of cells (e.g., fibroblasts, smooth muscle cells, endothelial cells, platelets, and monocytes) and is deposited locally. Fibronectin comes from a single gene, through alternative mRNA splicing. This gene encodes a large number of variants.

The FN molecule is a dimer which is comprised of 2 nearly identical polypeptides linked by 2 disulfide bonds at their C-termini (Fig. 1). Each monomer is composed of 3 types of homologous repeating units or modules (12 of type I, 2 of type II and 15–17 of type III) which create structurally and functionally independent domains with binding sites for ECM proteins (e.g., collagen), cell surface receptors (e.g., integrins, bacterial FN receptors, cytokines), blood proteins (e.g., fibrin), and glycosaminoglycans (e.g., heparin).

Fibronectin is encoded by a single gene which, through alternative splicing, generates 20 possible variants in humans. Protein diversity is obtained through the inclusion or exclusion of a type III homology segment (extra domain A of FN (EDA) and extra domain B of FN (EDB)) and by the presence of a V region (IIICS), which can be assembled in 4 ways or completely excluded. Plasma FN lacks extra EDA and EDB segments, and its V region is included in only 1 subunit. Cellular FN bears variable proportions of EDA and EDB segments. Both forms, pFN and cFN, are reported to be incorporated into the fibrillar network of the ECM.

Human FN is 5–9% sugars attached as N- and O-linked oligosaccharides. In the case of pFN, there are N-linked glycans located exclusively in the gelatin and cell-binding domain. O-glycans are present in the connecting segment between the fibrin–heparin-binding and collagen-binding domains, and in the V region. The oligosaccharide part of FN protects the molecule against proteolytic degradation, enhances FN affinity to gelatin and promotes adhesion and the spread of fibroblasts.

Fibronectin function

Fibronectin is involved in cellular processes such as cell adhesion, migration, growth and survival, and it is required for embryonic development. Plasma FN supports hemostasis and regulates thrombosis, and it significantly accelerates healing by limiting the extent of inflammation. As a key component of a fibrin clot, pFN supports hemostasis by being rapidly deposited at the injured vessel wall and by supporting platelet aggregation via pFN–fibrin complexes. The role of cFN is to form and maintain tissue architecture and to regulate cellular processes.

The EDA and EDB FN domains play an important role during embryogenesis, vascular development, cell migration, and cell differentiation. Only very low levels of FN with an EDA and/or EDB domain circulate in the blood plasma of healthy people. The inclusion of EDA domain in FN in adults is associated with pathological processes such as atherosclerosis, lung fibrosis, liver fibrosis, diabetes, and cancer. In contrast to EDA, no receptor for EDB has yet been identified in vivo, and the biological role of this domain has not yet been fully clarified. The research of Kraft et al. showed that EDB FN enhances bacterial removal by activating αvβ3 integrin.

Fig. 1. Fibronectin structure. Fibronectin is composed of a series of FNI repeats (white hexagons), FNII repeats (dark grey circles), conserved FNIII repeats (light grey triangles), and alternatively spliced FNIII repeats (EDA, EDB, and V). Types I, II, and III repeats are composed of 40, 60 and 90 amino acids, respectively. Binding domains for collagen, fibrin, heparin and cells are indicated.
Fibronectin matrix assembly

Fibronectin matrix assembly is a cell-dependent process, and fibril formation requires interactions of the N-terminal type I modules (FNII, III) of FN with cell surface receptors. Fibronectin has a number of cryptic sites which remain hidden when the protein exists in its globular, soluble form and which become exposed when FN undergoes conformational changes associated with fibril formation. The β1-integrin α5β1 is the major cell surface protein which controls FN assembly (Table 1), but other cell surface receptors apart from integrins also participate in FN matrix assembly. The integrins link the cell surface FN with the intracellular actin cytoskeleton, forming a connection which is crucial for FN matrix assembly. The binding of FN to integrins and other receptors induces a reorganization of the actin cytoskeleton and activates the intracellular signaling complex. Contractile forces aid in converting inactive FN into the active extended molecule, and a concentration of active FN dimers at integrin clusters promotes FN–FN interactions and fibril assembly.

Interaction of fibronectin with matrix components

Fibronectin assembly is initiated by binding of soluble FN to cell surface receptors (integrins) that induce conformational changes and expose cryptic binding sites in bound FN. Fibronectin fibrils formed in a process of assembly are a major component of the provisional extracellular matrix of tissues, and the FN matrix is involved in the deposition of other ECM molecules as collagens, fibrillin, fibulin, and tenasin-C. Shi et al. showed that the deposition of FN into the ECM regulates the deposition and remodeling of ECM collagen I, partially by regulating collagen I endocytosis. The binding of the integrin α5β1 and syndecan-4 to FN generates the adhesive signaling required for the replacement of damaged tissue. The tenasin-C which is expressed at the edges of the wound and contacts the fibrin–FN provisional matrix serves to inhibit FN-initiated signaling events by blocking syndecan-4 binding. Additionally, the FN matrix can sequester growth factors, including several vascular endothelial growth factors (VEGFs), transforming growth factor β1 (TGF-β1) and the latent complex of TGF-β1. Vascular endothelial growth factor binds to FN type III domains to promote cell proliferation. Fibronectin is a ligand for the TLR4 receptor (a member of the receptor family that regulates the NFκB-dependent synthesis of cytokines). Kelsh et al. showed that 2 type III domains of FN can activate TLR signaling to induce an inflammatory response in fibroblasts. In response to mechanical forces, the EDA and III-I domains of FN can unfold to either reveal or hide biological active sites in a matrix which are involved in FN polymerization, cell adhesion or bacterial colonization. FN-EDA and FNIII, individually activate the same signaling pathways in dermal fibroblasts to induce a similar signature of inflammatory genes. In the extracellular environment, FN interacts with the enzyme transglutaminase 2 (TG2). On the cell surface, TG2 acts as an integrin-binding co-receptor for FN, which promotes cell adhesion and migration. It has also been shown that TG2 interacts with the heparin sulfate chains of syndecan-4. This type of impact seems to be required in response to extensive tissue damage and ECM degradation. Increased TG2 expression during

EDA and EDB – isoforms of FN gene.
wound healing probably enhances the adhesive/signaling functions of cell surface TG2 and may compensate for deficiency in the integrin-dependent adhesion and assembly of FN matrices. Telci and Griffin suggest that TG2 protected from matrix metalloproteinases (MMPs) in a complex with FN is likely to ensure an adhesion-mediated cell survival mechanism in situations of matrix breakdown during wound healing.27 Fibronectin has the ability to form a cross-linked complex with FN fragments (FN type III domains) and can indeed participate in the exchange and/or addition of β-strands during the formation and maturation of FN fibrils.28

The involvement of fibronectin in inflammatory diseases and sepsis

Inflammation is a dynamic process characterized by the recruitment of leukocytes and plasma proteins from the blood into tissues, where the inflammatory response is activated to neutralize and eliminate potentially injurious stimuli, immune surveillance, optimal repair, and regeneration after injury.29 Dysregulation of these processes forms the background of many complex diseases (e.g., sepsis, infectious disease, trauma, allergy, autoimmune disorders, cancer, neurodegenerative diseases, and atherosclerosis).29 Sepsis is defined as a life-threatening organ dysfunction caused by a dysregulated host response to infection.30 It is a systemic inflammatory response to an infectious pathogen that may be significantly amplified by endogenous factors. Sepsis is now known to involve early activation of both pro- and anti-inflammatory responses, along with major modifications to non-immunological pathways such as cardiovascular, neuronal, autonomic, hormonal, bioenergetic, metabolic, and coagulation.30

Fibronectin has been shown to be involved in inflammation. In animals, it is a positive acute-phase protein, with higher blood levels during inflammation,31 but in humans, plasma FN is regarded as a negative acute-phase protein.32 Fibronectin promotes chemotaxis and influences leukocyte function.33 Additionally, Rossen et al. demonstrated that FN acts as a modulator of leukocyte function.34 In the case of sepsis, the role of FN in promoting the adhesion and infiltration of bacteria to human cells seems to be important.35

EDA-FN isoforms in inflammatory diseases

The main role of EDA-FN in adults is associated with wound healing,3 tissue fibrosis,3,8,25 thrombosis, and the maintenance of vascular wall integrity.5 The amount of the EDA isoform is very low or undetectable in the blood plasma of adults, but it significantly increases under pathological conditions such as fibrosis (in the lungs, liver and kidneys), diabetes, atherosclerosis, hypertension, ischemic heart disease, stroke, rheumatoid arthritis, and cancer. EDA-FN has also been recognized as a factor which promotes chronic inflammation.1,36 The main source of EDA is the smooth muscle cells of blood vessels.36

In atherosclerosis, the role of EDA-FN is twofold. On the one hand, the EDA-FN isoform is involved in the initiation and progression of atherosclerosis, but on the other hand, the presence of EDA-FN is associated with a better, more stable plaque phenotype.37 Similarly, in diabetes the EDA domain plays a dual role. It expands the extracellular matrix, resulting in diabetic structural vascular abnormalities, but prevents endothelial dysfunction by providing feedback defense against excessive generation of reactive oxygen species (ROS).38 Bhattacharyya et al. showed that the EDA domain of FN promotes chronic cutaneous fibrosis through the TLR-4 receptor.39 Additionally, several studies have demonstrated that the EDA domain (as well as the EDB domain) is highly expressed in many tumors, e.g., breast cancer,38 liver cancer,11 lung cancer,39 colorectal cancer,40 and bladder cancer.41 Both isoforms of FN are expressed by cancer cells, tumor-associated fibroblasts and newly forming blood vessels in angiogenesis. The data of von Au et al. showed that circulating FN plays an important role in tumor growth. Fibronectin content in the tumor correlates with the number of blood vessels and tumor growth in mouse models.41 Attieh et al. reported that cancer-associated fibroblasts induce invasion of cancer cells by FN assembly and integrin αvβ3 expression.31 An ongoing study related to the role of EDA-FN in sepsis showed that an absence of this isoform contributes to poor sepsis outcomes in a murine model.44

Fibronectin in sepsis

The potential pathological consequences of incorrect host defense against infection include autoimmunity, inflammatory tissue damage, organ dysfunction, and sepsis. The lack of sensitive diagnostic tests for sepsis combined with its various non-specific signs and symptoms makes diagnosis very difficult. Many biomarkers have been evaluated for application in sepsis, but none of them has sufficient specificity or sensitivity to be used in clinical practice. C-reactive protein (CRP), procalcitonin (PCT) and interleukin 6 (IL-6) are used only for additional assessments.45 Fibronectin is one of various sepsis biomarkers which have been proposed in the field of sepsis diagnosis. Martin et al. proposed that a plasma FN level lower than 120 mg/L could suggest a diagnosis of sepsis in its early stages. The lower level of pFN in patients who fulfill the criteria for a diagnosis of clinical sepsis may be associated with the constant reparatory process exerted by pFN.46 According to data from Reichsoellner et al., the highest levels of FN occur in patients with a systemic inflammatory response but with no blood infection; it is lower in patients with Gram-positive and Gram-negative bacteremia, and the lowest levels appear in fungemia.47
A decreased level of pFN is associated with acute inflammation, surgical trauma and disseminated intravascular coagulation. According to Mamani et al., decreased levels of pFN and increased levels of CRP may be considered reliable diagnostic markers for sepsis. Interestingly, during sepsis in animal plasma, pFN levels are higher.

The data from recent years about the increasing levels of EDA and EDB isoforms of FN in pathological conditions may be of more interest than pFN in relation to sepsis. As described above, the absence of the EDA-FN isoform contributes to poor sepsis outcomes in a murine model. However, Satoi et al. reported that the concentration of plasma EDA-FN in patients with sepsis who survived was significantly lower than that in non-survivors.

Fibronectin has been identified as the target for a large number of bacterial proteins generally considered to be adhesins; therefore, FN seems to play a prominent role in the pathogenesis of sepsis. Furthermore, FN-binding surface proteins are found in many bacterial species (e.g., Streptococcus pyogenes or Staphylococcus aureus). They promote the adhesion of bacteria to human cells and enter into them. The most common pathogens that cause sepsis include Staphylococcus aureus, Streptococcus, Enterobacteria (Escherichia coli, Klebsiella and Proteus), Neisseria meningitidis and Candida spp. Staphylococcus aureus is a commensal bacterium in humans and it causes a variety of diseases, including sepsis. Two FN-binding protein homologues – FnBPA and FnBPB – expressed by S. aureus, are involved in adhesion to the cell surface and internalization. Staphylococcus aureus associates through FnBP with the type I repeats of host-derived FN. The ligand-binding regions of FnBPs (Fig. 2) interact with a 29 kDa N-terminal region of FN (the fibrin/heparin binding domain consisting of FN type I1,2 repeats). Fibronectin deposited on the pathogen surface is recognized by the cellular FN receptor integrin α5β1, which binds to the RGD motif (a key motif responsible for cell binding) within this matrix protein. The additional bacterial binding sites on FN are located at the FNII13 module and FNII8/FNII10 modules. Nyberg et al. demonstrated that plasma FN bound to the bacterial surface downregulates the virulence of S. pyogenes by limiting bacterial spread. Kraft et al. reported that EDB FN enhances in vitro phagocytosis to a larger extent than plasma FN. Additionally, αvβ3 integrin (classically described as the vitronectin receptor) plays a direct role in bacterial phagocytosis in mammals.

The binding of FnBPs to FN mediates the adherence of S. aureus not only to extracellular matrices but also to the surface of a number of host cells, including endothelial cells, epithelial cells and fibroblasts. An additional aspect to which attention should be paid when discussing the role of FN in the processes of inflammation and sepsis is the activation of the coagulation system (Fig. 3). In sepsis, systemic inflammation permanently leads to activation of the coagulation system and inhibition of the anticoagulant mechanism and fibrinolysis.

Increased fibrin generation and impaired breakdown as a main result of upregulating plasminogen activation inhibitor type 1 both lead to the deposition of microvascular clots. Platelet activation is an alternative stimulation of fibrin formation and it plays an important role in the development of coagulation abnormalities in sepsis. Some blood plasma components, such as fibrinogen and fibrin, create high-molecular FN forms which may reflect changes in vascular endothelium and ECM remodeling in inflammatory diseases.

**Conclusions**

Fibronectin is a crucial ECM protein regulating ECM-dependent cell adhesion, migration and differentiation. Both plasma and cellular forms of FN play important roles during tissue repair. Plasma FN is a significant component of fibrin clots, taking part in hemostasis stabilizing the clot structure, provisional matrix formation and the repair process. Cellular FN supports efficient platelet adhesion, activation, aggregation, and pro-coagulant activity. The deposition of FN into the ECM regulates the inclusion and remodeling of ECM collagen I, in part by regulating collagen I endocytosis. In addition to the plasma FN, isoforms of cellular FN play a key role in pathology. An elevated EDA-FN level is associated with clinical conditions, including diabetes and atherosclerosis, and may result in increased thrombosis in patients at a high risk.
of cardiovascular events. Many microbial pathogens invade the host by expressing surface receptors that bind specifically to FN, and – as Nyberg et al. have shown – pFN bound to the bacterial surface downregulates virulence by limiting bacterial spread. The binding of FN to integrin induces a reorganization of the actin cytoskeleton and activates the intracellular signaling complex. Integrins, along with lipopolysaccharide, are key receptors of phagocytes. The EDB-FN isoform of cFN enhances phagocytosis more than pFN.

In summary, as shown previously, FN plays an important role in the host response to infection, being involved in maintaining vascular integrity, wound healing and triggering the blood clotting process. Additionally, it mediates important interactions with phagocytes throughout the inflammatory process, and as part of a 3-component bridge, FN contributes to bacterial colonization of endothelial and epithelial cells. The understanding of the role of FN in inflammation, especially its EDA and EDB isoforms, seems to be crucial to the understanding of how FN could help in the development of therapeutic strategies to treat inflammatory diseases, including sepsis.
