Abstract

**Background.** *Chlamydia* infection is the most frequently reported infectious, sexually transmitted disease (STD). Generally, *Chlamydia trachomatis* (*C. trachomatis*) infection of neonates is the result of perinatal exposure to the mother’s infected cervix.

**Objectives.** The aim of the study was to estimate the frequency of infection caused by *C. trachomatis* in newborn infants. In this study of *C. trachomatis* perinatal infection, 107 infants born at the Wroclaw Medical University Clinic of Gynecology and Obstetrics (Poland) were tested to investigate whether *C. trachomatis* was present in swabs taken from the eyes and throats of children.

**Material and methods.** Each specimen was tested using the direct immunofluorescence test (DIF) and the nested polymerase chain reaction (PCR) method.

**Results.** The presence of *C. trachomatis*, irrespective of the origin of the swabs (ocular or from the throat), was confirmed in 62 newborns, amounting to 57.6% of the tested population. The occurrence of *C. trachomatis* in ocular swabs was confirmed in 35 children (32.7%). In the material taken from the throat, there were 48 newborns considered chlamydia-positive (44.9%). In the specimens taken from both the ocular and pharyngeal locations, there was a higher proportion of positive results while using the nested-PCR method in comparison to the DIF test. The specificity of the DIF method with reference to the nested-PCR was 67.9% for ocular swabs. In the material taken from the throat, the sensitivity of the DIF method with reference to the nested-PCR was 75.0% and the specificity was 62.1%.

**Conclusions.** Because of the importance of perinatal infections, it is recommended to perform a study among a larger group of patients in order to gain more reliable results.

**Key words:** Chlamydia trachomatis, infection, newborn
Introduction

Infections of *Chlamydia trachomatis* (*C. trachomatis*), caused by oculogenital serotypes D–K, are among the most common sexually transmitted diseases (STDs). It is estimated that there are approx. 100 million new cases of *C. trachomatis* infection every year worldwide.1 As long as chlamydia is the most commonly reported STD in the United States, it is recommended that annual screening examinations are carried out there in sexually active women under the age of 25 years, or in older women who are at an increased risk of infection.2–4 Moreover, it is suggested that pregnant women in this age group undergo testing for *C. trachomatis* during their 3rd trimester of pregnancy.4

The oculogenital serovars (D–K) of *C. trachomatis* in newborn infants may be responsible for developing conjunctivitis and interstitial pneumonia, with conjunctivitis occurring more frequently. These include perinatal infections that take place during the passage of the newborn infant through the infected mother’s cervix.5,6 However, 1 case of *C. trachomatis* conjunctivitis was reported in a newborn infant delivered by cesarean section, which argues in favor of intrauterine infection by the continuity of tissues.6 The risk of *C. trachomatis* perinatal infection in newborn infants is estimated at approx. 30%.5

A chlamydial etiology should be considered if the mother was infected in the past. Neonatal conjunctivitis occurs in 18–50% of children of infected mothers, with frequent occurrence in preterm infants, who are at risk, since chlamydia infections may cause premature labor.7 The infection develops up to 3 weeks after birth and may become chronic. Its characteristic symptoms include mucopurulent discharge from the conjunctival sac with accompanying swelling and redness, but the infection can also be asymptomatic. Conjunctivitis, if left untreated, may lead to blindness.8

*Chlamydia trachomatis* conjunctivitis and pneumonia coexist in up to 1/2 of ill newborn infants. Interstitial pneumonia develops between the 3rd and the 12th week of age, and can vary in intensity. In most cases, the disease is mild, but breathing disorders may at times require oxygen therapy. High levels of eosinophils can be reported in the blood. A large number of B lymphocytes and plasma cells in the blood, which is characteristic for *C. trachomatis* pneumonia, results in high levels of immunoglobulin M (IgM) antibodies in the blood. The changes can be seen in spirometry and in radiological examination. The symptoms include a dry cough, a low-grade fever and rapid breathing.6,7 It is suspected that *C. trachomatis* infection may be related to sudden infant death syndrome (SIDS).7,10

Infrequently, *C. trachomatis* in newborn infants can cause infections of the vagina, rectum, nasopharynx, or middle ear.

Aim of the study

The aim of the study was to estimate the frequency of infection caused by *C. trachomatis* in newborn infants.

Material and methods

The experimental material consisted of swabs collected from newborn infants at the 1st Department and Clinic of Gynecology and Obstetrics (Wroclaw Medical University, Poland). A total of 109 children were tested. Four swabs were collected from every newborn infant: 2 from the eye and 2 from the throat. We used a direct immunofluorescence test (DIF) – Chlamydia Pathfinder (Bio-Rad Laboratories, Marnes-la-Coquette, France) and the nested polymerase chain reaction technique (nested-PCR) – PCR-Chlamydia trachomatis test (DNA Gdańsk, Poland) in order to detect chlamydia infection. Two hundred and eighteen tests were conducted by DIF (109 eye swabs and 109 throat swabs), and the same number of tests was done by nested-PCR. All tests were performed in the Chlamydia Research Laboratory, Department of Basic Sciences, Wroclaw Medical University, Poland.

The quality of the tested material is of great diagnostic importance in the case of *C. trachomatis*. Due to the fact that chlamydiae are obligate intracellular parasites, the obtained material must contain epithelial cells. Detecting bacteria in the absence of epithelial cells provides unreliable results. Neither eye fluid nor saliva constitute suitable test material.

Since epithelium was not detected in the swabs taken from 2 patients, we did not take into account the results from these samples. Altogether, we analyzed 428 results. The swabs were collected by authorized personnel in accordance with the appropriate procedures.

The analysis of results was performed using the statistical package PQStat v. 1.6.0.428 (PQStat Software, Poznań, Poland).

Comparing the results of the eye swabs to those of the throat swabs, the measure of compliance was applied. Comparing the results of the DIF method in reference to the gold standard – the PCR method – the results of compliance, sensitivity, specificity, and positive and negative predictive value were specified, and 95% confidence intervals (CI) were estimated for these results. Compliance measurements were also analyzed with McNemar’s test.

A probability of *p* < 0.05 was determined to be significant and a level of *p* < 0.01 was determined to be highly significant.

Results

We found chlamydia in both the eye and throat in 19.6% of all newborn infants (21 patients). Chlamydia was not detected at all in 42.1% of newborn infants (45 patients).

In the material taken from both the eye and throat, there was a significantly higher percentage of positive results obtained by nested-PCR (34/107 for the eye; 45/107 for the throat) than by DIF (1/107 for the eye; 12/107 for the throat) (Table 1).
The presence of *C. trachomatis* in eye swabs was reported in 35 newborns, i.e., in 32.7% of patients. There was only 1 positive result in DIF. In this sample, the nested-PCR results were negative, which is equivalent to the lack of consistently positive results in eye swabs. We reported 72 consistently negative results (68.2%) and 35 inconsistently negative results (32.7%) (Table 2).

In 6 newborn infants, we reported symptoms related to eye infection, whereas in 3 newborns (50.0%), we reported positive results from the eye, and in 1 case from the throat alone. In 2 patients, we found negative results despite the occurrence of symptoms.

In patients with eye or respiratory symptoms, we obtained positive results mainly by nested-PCR. In most of these cases, in both the throat and eye, DIF testing gave negative results (in all 6 newborns with ocular symptoms and in 6 out of 7 newborns with respiratory symptoms). We carried out a follow-up examination in 16 newborn infants (15.0%). *Chlamydia trachomatis* was confirmed in 9 cases (56.3%) by nested-PCR, while there were no positive DIF results.

The compatibility (accuracy) of diagnosis for both methods equaled 87.85% (95% CI: 80.12–93.37%), which refers only to the “negative” results. However, in any case, the “positive” results were not consistent in both measurements. This is mainly due to the fact that the DIF method for eye swabs showed only 1 positive result. Among the results obtained by the DIF method for the throat, 12 positive results were reported. The results of McNemar’s compliance test indicated a significantly high level of inconsistency of the results for both measurements ($\chi^2 = 7.69$; degree of freedom [df] = 1; $p = 0.0055$) (Table 4).

The compatibility (accuracy) of diagnosis for both methods equaled 65.42% (95% CI: 55.61–74.35%), and this result is the sum of consistent negative results (45.79%) and consistent positive results (19.63%). The results of McNemar’s compliance test indicated an insignificant level of differences in both measurements ($\chi^2 = 2.70$; df = 1; $p = 0.1002$), so both measurements can be considered compatible (Table 5).

The compatibility (accuracy) of diagnosis for both methods equaled 67.29% (95% CI: 57.54–76.05%), which refers only to the “negative” results. However, in any case, the “positive” results were not consistent in both measurements. This is mainly due to the fact that the DIF method for the eye swabs showed only 1 positive result. Among the results obtained by the PCR method for the eye, there were 34 positive results. Accordingly, the sensitivity of the DIF method for the eye compared to the PCR method for the eye equaled 0%; the specificity equaled 98.63%.

In 6 newborn infants, we reported symptoms related to eye infection, whereas in 3 newborns (50.0%), we reported positive results from the eye, and in 1 case from the throat alone. In 2 patients, we found negative results despite the occurrence of symptoms.
M. Frej-Mądrzak, et al. C. trachomatis infection in neonates

The positive predictive value was 0% and the negative predictive value was 67.92% (95% CI: 58.16–76.66%). The results of McNemar’s compliance test indicated a significantly high lack of consistency of results for both measurements ($\chi^2 = 29.26; df = 1; p < 0.0001$). The compatibility (accuracy) of diagnosis for both methods equaled 63.55% (95% CI: 53.69–72.64%), and this result is the sum of consistent negative results (55.14%) and consistent positive results (8.41%). The sensitivity of the DIF method for throat swabs comparing to the reference method (PCR) was 20% (95% CI: 9.58–34.60%) and the specificity was 95.16% (95% CI: 86.50–98.99%). The positive predictive value was 75% (95% CI: 42.81–94.51%) and the negative predictive value was 62.10% (95% CI: 51.57–71.86%). The results of McNemar’s compliance test indicated a significantly high lack of consistency of results for both measurements ($\chi^2 = 26.26; df = 1; p < 0.0001$) (Table 7). When testing the sensitivity and specificity, PCR and DIF methods were compared, the compliance of positive and negative results obtained with these methods in the same patients.

### Discussion

Researchers rarely raise the subject of the occurrence of *C. trachomatis* in newborn infants, but studies carried out on newborn infants born to healthy mothers are even less frequent. This may result from the fact that conjunctivitis, the most common form of chlamydia in newborn infants, usually presents mild symptoms and can resolve spontaneously. Another reason may be associated with the reluctance of some parents to take material from their children if there is no such need. Swabs, washes or aspirates from the nasopharynx and eyes are commonly used in diagnosing *C. trachomatis* infections in children. Competent eye or throat swabbing, even if it causes the child’s discomfort, is necessary to achieve research reliability.

In 2012 and 2013, in order to diagnose perinatal infections, Frej-Mądrzak et al. examined the material collected from 55 children.11 The authors chose DIF as the research technique. The material included 33 eye swabs, 19 throat swabs and 11 urethra swabs. The authors reported 1 positive result in the throat swab (1.8%).
In Buenos Aires, between July 1995 and December 1998, Di Bartolomeo et al. examined 332 newborns diagnosed with conjunctivitis. The chosen method of research was the enzyme-linked immunosorbent assay (ELISA) technique. Positive results were confirmed by nested-PCR. The authors detected *C. trachomatis* in 7.8% of cases, which was the only pathogen detected in 22 out of 26 children. The authors detected other bacteria in 4 cases, but they did not have any significance as to the type of infection. The authors reported decreased occurrence of chlamydial conjunctivitis throughout the study period; in 1995, this number amounted to 4.4 cases per 1,000 live births, and in 1998 to only 0.8 cases per 1,000 live births. In our own research, which studied newborn infants at the 1st Department and Clinic of Gynecology and Obstetrics of Wroclaw Medical University, we reported a very high percentage of patients (57.9%) with positive laboratory test results for *C. trachomatis*. When analyzing the test results from throat and eye swabs, we noted that chlamydiae were slightly more frequently detected in the throat.

At the time of carrying out this review, we did not find any new data on the subject regarding simultaneous examination of throat and eye swabs with the same research techniques. Therefore, we found it difficult to refer to individual authors. Considering the importance of this subject, we suggest conducting studies on a larger group of patients in order to draw statistically relevant conclusions.

**Conclusions**

The detection of 48 cases of *C. trachomatis* infection in swabs from the throat and 35 cases in swabs from the eye by the PCR method suggests that tests detecting *C. trachomatis* in pregnant women should be included in routine diagnosis before giving birth. These examinations should be applied also to newborns whose mothers were diagnosed with chlamydia in the past in order to avoid the complications of perinatal infection by this pathogen.

In summary, the results obtained by the DIF method are not compatible with the reference results obtained by the PCR method. The DIF method is not diagnostically reliable.
