Abstract

Background. Exposure to lead (Pb) in environmental and occupational settings continues to be a serious public health problem and may pose an elevated risk of genetic damage.

Objectives. The aim of this study was to assess the level of oxidative stress and DNA damage in subjects occupationally exposed to lead.

Material and methods. We studied a population of 78 male workers exposed to lead in a lead and zinc smelter and battery recycling plant and 38 men from a control group. Blood lead levels were detected by graphite furnace atomic absorption spectrophotometry and plasma lead levels by inductively coupled plasma-mass spectrometry. The following assays were performed to assess the DNA damage and oxidative stress: comet assay, determination of 8-hydroxy-2’-deoxyguanosine (8-OHdG), lipid peroxidation and total antioxidant status (TAS).

Results. The mean concentration of lead in the blood of the exposed group was 392 ± 103 µg/L and was significantly higher than in the control group (30.3 ± 29.4 µg/L, p < 0.0001). Oxidative DNA damages measured by comet assay showed no significant differences between populations. The concentration of 8-OHdG was about twice as high as in the control group. We found a significant positive correlation between the level of biomarkers of lead exposure [lead in blood, lead in plasma, zinc protoporphyrin (ZPP)] and urine concentration of 8-OHdG. The level of oxidative damage of DNA was positively correlated with the level of lipid peroxidation (TBARS) and negatively with total anti-oxidative status (TAS).

Conclusions. Our study suggests that occupational exposure causes an increase in oxidative damage to DNA, even in subjects with relatively short length of service (average length of about 10 years). 8-OHdG concentration in the urine proved to be a sensitive and non-invasive marker of lead induced genotoxic damage.

Key words: oxidative stress, lead exposure, DNA damage, comet assay, 8-hydroxy-2’-deoxyguanosine
Exposure to lead (Pb) in the environmental and occupational settings continues to be a serious public health problem. Pb causes a number of adverse effects on many systems of the body like hematopoietic, renal, hepatic, bone, nervous, cardiovascular and reproductive systems. Exposure to Pb may pose an elevated risk of genetic damage. Subjects occupationally exposed to lead compounds have an increased risk of cancer, lung and gastric in particular.2,3

One of the recognized mechanisms of lead toxicity is the induction of oxidative stress. Excessive generation of ROS (Reactive Oxygen Species) is caused by the inhibition of δ-ALAD (δ-aminolevulinic acid dehydratase) by lead. As a result of this, there is an increased accumulation of δ-ALA (aminolevulinic acid), which undergoes enolization and auto-oxidation and generates hydrogen peroxide and superoxide radical, and also interacts with oxyhemoglobin. The final oxidation product of δ-ALA, 4,5-dioxyvaleric acid, is an effective alkylation agent of the guanine in DNA. The generation of potentially genotoxic compound is a possible mechanism for the metal-dependent DNA carcinogenicity of lead.4 The lead-induced generation of ROS results in the attack of polyunsaturated fatty acid residues of phospholipids, which are extremely sensitive to oxidation. The main product of peroxidation process is malondialdehyde (MDA). MDA can react with DNA bases (G, A and C) and form adducts. M1G (pyrimido [1,2-a] purin-10(3H)-one), a major endogenous DNA adduct in (G, A and C) and form adducts. M1G (pyrimido [1,2-a] purin-10(3H)-one), a major endogenous DNA adduct in humans is mutagenic and may lead to the formation of DNA-DNA crosslinks or DNA-protein crosslinks.5 Significant elevated levels of lipid peroxide in the plasma, even among workers exposed to low concentrations of lead, has been observed.6

Most oxidative DNA damage is caused by very reactive hydroxyl radical, which is known to react with all components of the DNA molecule. The effects of oxidative DNA damage are GC/TA transversions, single strand breaks, double strand breaks, generation of apurinic/apyrimidinic sites and DNA-DNA crosslinks. This kind of damages can result in the arrest or induction of transcription, induction of signal transduction pathways, replication errors and genomic instability, all of which are associated with carcinogenesis and mutagenesis.5,6

Comet assay is a simple, rapid and sensitive method for measuring DNA damage, such as single-strand DNA breaks (SSB), double-strand DNA breaks (DSB), alkali labile sites (apurinic/apyrimidinic sites), crosslinks and incomplete DNA repair sites.7,8 A modified version of comet assay with an addition of formamidopyrimidine glycosylase (FPG) can be used for the detection of DNA damage induced by reactive oxygen species.9,10 Hydroxyl radical reacts with all the nucleobases of DNA, but most frequently causes damage to guanine. This leads to the formation of 8-OHguanine (8-OHGua) or deoxyguanosine (8-hydroxy-2′-deoxyguanosine, 8-OHdG), its nucleoside form. The formation of 8-OHdG is caused by the weakening of the antioxidant system of the organism, as well as the imprecise repair of the damaged nucleic acid. 8-OHdG is promutagenic, and thus may be used as a potential biomarker of increased risk of carcinogenesis.11

Detection of those early, adverse changes in cells caused by exposure to lead allows us to undertake prevention measures reducing the health risks for employees. For this reason, the present study was carried out to assess the level of oxidative stress, in markers of oxidative DNA damage (urinary 8-OHdG levels, comet assay) in subjects occupationally exposed to lead.

Inhibition of ferrochelatase activity by lead prevents the incorporation of iron into protoporphyrin and the formation of heme. This leads to binding of zinc (Zn) and the production of zinc protoporphyrin (ZPP). An increase in ZPP production has been recognized to be an early biological effect of lead exposure and has been frequently used in health effects monitoring for lead exposure.1,4,12 Concentration of lead in blood is a result of both current and long term exposure.13

Another aim of our study was to analyze the correlation between the Pb exposure markers (lead in blood (B-Pb), ZPP) and markers of oxidative stress, DNA damage and level of antioxidative defence (total antioxidative status, TAS).

Subjects and methods

Study population

We studied a population of 78 male workers (aged from 20 to 62 years, mean age 36.4 ± 8.6 years) employed in lead and zinc smelter and battery recycling plant, exposed to lead. They were exposed to lead for 10.5 ± 8.3 years (0.8–35 years). The control group consisted of 38 men (aged from 19 to 61 years, mean age 35.0 ± 10.4 years) with no history of occupational exposure to lead, who were working for 11.6 ± 9.0 years (0.5–38 years). Only environmental exposure to lead occurred in the control group. Based upon questionnaire data, neither the exposed nor control group suffered from any acute or chronic disease, nor were alcohol addicted.

We used urine and blood samples collected in PHIME project (FOOD-CT-2006–016253) in 2009–2010. Blood was collected by venipuncture into sterile tubes containing either lithium heparin or ethylenediamine-tetraacetic acid (EDTA) solution as an anticoagulant. Blood samples were stored at -20°C and urine at -80°C until required for analysis. The protocol for this project has been approved by Bioethics Committee at Institute of Occupational and Environmental Health. All subjects gave informed consent.
Lead intoxication parameters

B-Pb levels were detected by graphite furnace atomic absorption spectrophotometry using Perkin-Elmer 4100ZL instrument. The laboratory participates in internal and inter-laboratorial proficiency tests (CDC in Atlanta, USA). ZPP levels were measured in whole blood using a haematofluorometer. The concentrations of B-Pb were quantified as µg/L and ZPP as µg/g Hb.

The concentrations of lead in plasma (P-Pb) were determined in samples diluted 5 times with an alkaline solution, according to Barany et al., by inductively coupled plasma-mass spectrometry (ICP-MS; Thermo X7, Thermo Elemental, Winsford, UK). The detection limit, calculated as 3 times the standard deviation (SD) of the blank, was 0.06 µg/L. All analyzed samples were prepared in duplicate and the method imprecision (calculated as the coefficients of variations in measurements of duplicate preparations) was 2.5%. To ensure analytical accuracy, quality control samples were analyzed along with the collected samples. The results obtained (mean ± SD) were 0.99 ± 0.08 µg/L (n = 9) vs recommended 1.02 µg/L (Seronorm Elements Serum, lot 0903106; SERO AS, Billingham, Norway) and 9.3 ± 0.46 µg/L (n = 9) vs recommended 8.2 ± 0.83 µg/L (Centre de Toxicologie du Quebec, International Comparison Program, Quebec, Canada; lot QMEQAS068–06).

Comet assay method

The DNA damage was analyzed in whole blood using alkaline comet assay according to the method by Singh et al. with some modification and FPG-modified comet assay, as previously described.15,16 Briefly, 40 µL of whole blood in 1% low melting point agarose (Sigma) was placed on a microscope slide that had been pre-coated with 0.5% normal melting point agarose (Sigma). Coverslips were placed on the gels, and the slides with coverslips were put on ice. Then coverslips were removed and the slides were submerged in lysis solution (2.5 mol L⁻¹ NaCl, 10 mmol L⁻¹ EDTA, 0.5 mmol L⁻¹ Tris, 1 % Triton X-100, pH = 10) at 4°C in the dark. After 1 hour, the slides were washed 3 times with enzyme reaction buffer (4 mmol L⁻¹ Hepes, 0.1 mol L⁻¹ KCl, 0.5 mmol L⁻¹ EDTA, 0.2 mg/mL BSA) at 4°C for 5 min each. Then slides were treated with 70 µL of FPG solution (New England Biolabs) or buffer alone as control. The enzyme was diluted right before use. The slides were washed 3 times with a neutralization buffer (0.4 mol L⁻¹ Tris-HCl, pH = 7.5), dried and stained with DAPI (4,6-diamidino-2-phenylindole) solution (1 µg/mL). The slides were stored in a closed humidi chamber at 4°C for 20 h. Slides were prepared in duplicate per person and analyzed by image analysis system Comet v. 5.5 (Kinetic Imaging Ltd., Liverpool, UK). 75 cells were calculated per 1 person (2 slides). To quantify DNA damage, the following comet parameters evaluated the percentage of DNA in the tail (relative fluorescence intensity of tail; TI), tail length (distance from head center to the end of the tail; in m) and tail moment (TM), which was calculated as tail length × percentage of DNA in tail (in arbitrary units). The control slides (no enzyme treatment) provided an estimate of the background of DNA strand breaks. The enzyme-treated slides revealed strand breaks and oxidized bases (total DNA damage).

DNA damage in urine

Detection of 8-OHdG was performed using ready-to-use ELISA-based assay (Cat. RSCN213100R, BioVendor) according to the manufacturer’s instructions. Samples of urine and 8-OHdG standards were added to a 96-well plate which has been precoated with 8-OHdG. Then, the 8-OHdG monoclonal antibody was added and the plate was incubated at 37°C for 1 h. Next, the plate was washed and incubated with secondary antibody labeled with horseradish peroxidase at 37°C for 1 h. The plate was washed thrice and substrate solution was added and incubated for 15 min at room temperature before a stop solution (1M phosphoric acid) was added. Spectrophotometric readings were obtained at 450 nm by using BIO-TEK PowerWave XS microplate reader (BIO-TEK Instruments). The concentration of 8-OHdG in urine was determined using a standard curve. The level of 8-OHdG was expressed as ng/g creatinine.

Determination of lipid peroxidation

Urine levels of lipid peroxides were determined as TBARS using Cayman TBARS Assay Kit (Cat. 10009055 Cayman Chemical, USA). The MDA-TBA adduct formed by the reaction of MDA and TBA under high temperature (90–100°C) and acidic conditions were measured colorimetrically at 530–540 nm using the BIO-TEK PowerWave XS microplate reader (BIO-TEK Instruments). The concentration of MDA was determined using an MDA standard curve. Results were expressed as µmol MDA per liter and µmol MDA per gram of creatinine. Typically, normal human urine has a lipid peroxide level of 0.8–2.0 µmol/g creatinine.
Total antioxidant status (TAS)

TAS was measured in urine using the Antioxidant Assay Kit (Cat. 709001, Cayman Chemical) following the manufacturer’s instruction. This assay relies on the ability of the antioxidants in the sample to inhibit the oxidation of 2,2-azino-di- [3-ethylbenzthiazoline sulphonate] (ABTS) to ABTS+ radical by metmyoglobin. The amount of ABTS+ was monitored by reading the absorbance at 750 nm. The antioxidants in the sample caused the suppression of the absorbance to a degree which was proportional to their concentration. The capacity of the antioxidants in the sample to prevent ABTS oxidation was compared with that of Trolox, a water-soluble tocopherol analogue and was quantified as milimolar Trolox equivalents. The plate reader used was BIO-TEK PowerWave XS (BIO-TEK Instruments).

Statistical analysis

The STATISTICA v. 9.PL was used for data analysis. The Shapiro-Wilks test was used to verify normality. The significance of difference between the exposed and control group was determined using the Mann-Whitney U test as the data distribution was non-parametric. Spearman’s non-parametric correlation was used to find out the correlation between study parameters. The probability values of p < 0.05 were considered significant.

Results

Table 1 presents the characteristics of the exposed and control groups. No statistical differences in age and body weight were found between the groups. The percentage of smokers was evenly distributed within both groups.

The mean concentration of lead in blood in exposed group was 392 ± 103 µg/L and was significantly higher than in control group (30.3 ± 29.4 µg/L, p < 0.0001).

The differences between study groups were also significant (p < 0.001) according to lead level in plasma and ZPP, which were higher among occupationally exposed subjects (Table 2). The results of biomarkers of oxidative stress demonstrated that subjects exposed to lead had a lower level of antioxidant status and higher levels of TBARS and 8-OHdG, but only the latter was significantly different compared to control group (p = 0.01).

Oxidative DNA damages measured by FPG-modified comet assay showed no significant differences between populations.

Correlations between the studied parameters are shown in Table 3. Lead intoxication parameters significantly correlated with each other. We found a positive correlation between biomarkers of lead exposure (B-Pb, P-Pb, ZPP) and DNA damage in urine. The level of lipid peroxidation (TBARS) was found to be significantly cor-

related with oxidative DNA damage measured by comet assay. The negative correlations were observed between tail intensity, tail length, tail moment and TAS.

Discussion

A safe level of lead exposure is very hard to define because health risks associated with lead are found at even low doses.13 The permitted biological concentration of
and ZPP) and the level of oxidative damage of DNA in urine (concentration of 8-OHdG). Our results are in line with earlier findings that occupational exposure even to low levels of lead as well as to levels not exceeding the permissible levels increases the risk of genetic damage. 17,18

We have observed also an inverse relationship between oxidative damage, measured as change in tail intensity, tail length, tail moment between FPG modification and standard comet assay, and antioxidative potential (TAS) in serum, and positive correlation between level of lipid peroxidation (TBARS) and levels of DNA damage (measured based on both comet method as well as based on 8-OHdG levels in urine). Those results confirm the relationship between a weakened antioxidative defence and oxidative stress induced by various factors, including Pb, and the effects of genotoxic, observed also by other authors. 5,19

Genotoxic effects may be modulated by many factors affecting studied subjects, such as cumulated exposure to lead, genetic predispositions, health, nutrition, smoking, drinking alcohol and other present in the environment, causing damage to the genetic material. 20

Polymorphic genes taking part in pollution metabolism or in DNA repair processes may control the degree of damage caused by exposure to genotoxic factors and increase the risk of cancer and other diseases. 21 Coelho et al.

Spearman’s R values *p < 0.05; **p < 0.01; ***p < 0.001; ns – non significant; 8-OHdG – 8-hydroxy-2’-deoxyguanosine; Δ – change; B-Pb – blood lead level; FPG – formamidopyrimidine glycosylase assay modification; P-Pb – plasma lead level; TAS – total antioxidative status; TBARS – thiobarbituric acid reactive substances – lipid peroxidation; TI – tail intensity; TL – tail length; TM – tail movement; ZPP – zinc protoporphyrin.
observed significantly increased levels of DNA damage biomarkers in people environmentally and occupationally exposed to metals/metaloids.21 Those effects were correlated with internal doses of exposure and were more common in sensitive genotypes. Gene polymorphisms may influence the rate and efficiency of recovery and thus shape the individual sensitivity to Pb in the environment.

The choice of the method of measurement used to assess the level of DNA damage is equally important. The comet method gives the possibility of detecting DNA damage at the single cell level, identifying DNA breaks and chemical and enzymatic modifications that can be converted into breakage of DNA or chromatids. The comet assay can analyze any tissue which can provide cell suspension.7,10

The comet assay has been used in numerous studies to evaluate genotoxicity associated with lead exposure.16,22–26 Most of them reported increased levels of DNA damage measured by comet assay parameters in exposed workers with regard to controls. In our study, the comet assay did not show a significantly higher incidence of oxidative DNA damage in exposed workers compared to the control group. Although the tail length was widely used in different biomonitoring studies, it has been criticized due to the sensitivity to the background and threshold setting of the image analysis program.9,10 The divergences can also be explained by differences in the methodology, the characteristics of the populations studied and different biological material used for analysis. We have performed our assay in whole blood, while in the above-mentioned reports the damage was studied in isolated leukocytes.

Steinmetz-Beck et al. suggest a positive linear correlation between the concentration of lead in the blood and the values of comet parameters.27 We did not observe this relation; however, we found a positive correlation between B-Pb and 8-OHdG concentration in urine. In our study, the exposed group mainly consisted of young people with a rather short length of service and the B-Pb was lower than in the group measured by Steinmetz-Beck and co-authors. The average time of exposure to lead was equal to 10.5 ± 8.3 years and the age 36.5 ± 8.6 years vs 19 ± 7.1 (length) and 46.7 ± 8.6 (age) respectively. Also, Olewińska et al. observed associations between B-Pb and 8-OHdG formation in urine was significantly higher in Pb exposed subjects compared to the control group (administrative staff) was about 9 times lower (35.4 ± 4.3 µg/L); however, there are no differences in the values of the comet parameters between these groups.29 There was a significant increase in the frequency of mutations in the T-cell receptor (TCR -MF) in subjects exposed to Pb compared to control group. According to these authors, the changes detected in the TCR mutation assay are a result of an earlier long-term exposure taking place from several months to 2–3 years before the measurement, and the comet assay reflects the more recently formed damage, which is quickly repaired. Thus, the differences between the control group and the Pb exposed, assayed by comet method, are not always significant.

The urinary excretion of 8-OHdG has been used as a biomarker to assess the extent of repair of ROS-induced DNA damage in both the clinical and occupational setting. 8-OHdG forms a alkali pair with cytosine and adenine and increases the rate of spontaneous mutations incorporated into DNA. 8-OHdG is considered to be a useful marker of oxidative damage of DNA, increased risk of carcinogenesis and the development of degenerative diseases.11,18

In our study, 8-OHdG analysis in the urine was a more sensitive method of measuring genetic damage associated with occupational exposure to Pb compared to the comet method. As previously mentioned, 8-OHdG level in urine was significantly higher in Pb exposed subjects when compared to control subjects, and additionally this level positively correlated with the concentration of lead in plasma and the level of lipid peroxidation.

In summary, our study suggests that occupational exposure to Pb causes an increase in oxidative damage to DNA, which, in turn, increases the risk of carcinogenesis. These changes were observed in subjects with relatively short length of service (average length of about 10 years) and with significantly lower than the permissible limit
of lead concentration in the blood. 8-OHdG concentration in the urine proved to be a sensitive and non-invasive marker of lead induced genotoxic damage.
